

INVARIANT MEASURE OF ROTATIONAL BETA EXPANSION AND TARSKI'S PLANK PROBLEM

SHIGEKI AKIYAMA AND JONATHAN CAALIM

ABSTRACT. We study invariant measures of a piecewise expanding map in $\mathbb{R}^m$ defined by an expanding similitude modulo lattice. Using the result of Bang [5] on the plank problem of Tarski, we show that when the similarity ratio is not less than $m + 1$, it has an absolutely continuous invariant measure equivalent to the m -dimensional Lebesgue measure, under some mild assumption on the fundamental domain. Applying the method to the case $m = 2$, we obtain an alternative proof of the result in [1] together with some improvement.

1. INTRODUCTION

Let $1 < \beta \in \mathbb{R}$. Fix an isometry M from the orthogonal group $O(m)$ of dimension m . Let $\mathcal{L}$ be a lattice of $\mathbb{R}^m$ generated by η_i ($i = 1, 2, \dots, m$) and choose a standard fundamental domain

$$\mathcal{X} = \left\{ \xi + \sum_{i=1}^m x_i \eta_i \mid x_i \in [0, 1) \right\}$$

with a fixed translation $\xi \in \mathbb{R}^m$. Then

$$\mathbb{R}^m = \bigcup_{d \in \mathcal{L}} (\mathcal{X} + d)$$

is a disjoint partition of $\mathbb{R}^m$. Define a map $T : \mathcal{X} \rightarrow \mathcal{X}$ by $T(z) = \beta Mz - d$ where $d = d(z)$ is the unique element in $\mathcal{L}$ satisfying $\beta M(z) \in \mathcal{X} + d$. We obtain an expansion

$$\begin{aligned} z &= \frac{M^{-1}(d_1)}{\beta} + \frac{M^{-1}(T(z))}{\beta} \\ &= \frac{M^{-1}(d_1)}{\beta} + \frac{M^{-2}(d_2)}{\beta^2} + \frac{M^{-2}(T^2(z))}{\beta^2} \\ &= \sum_{i=1}^{\infty} \frac{M^{-i}(d_i)}{\beta^i} \end{aligned}$$

with $d_i = d(T^{i-1}(z))$. We call T the *rotational beta transformation* in $\mathbb{R}^m$.

The rotational beta transformations extend the notion of beta expansions [27, 24, 12] and negative beta expansions [11, 13] to higher dimensions. The classical beta expansions are themselves generalizations of the decimal expansion. There is an enormous literature dealing with problems relating non-integer representations of numbers in $\mathbb{R}$ and in higher dimensional spaces. Canonical number systems [8, 14, 31, 2] give representations of higher dimensional points using positive integer bases with little redundancy, that is, the set of points with more than one representation has Lebesgue measure zero. Disregarding this redundancy, it is also of interest to study representability of all complex numbers closed to the origin using a finite set of complex digits. This theme is repeatedly studied, for instance, in [20, 28]. The notion of rotational beta expansions, in the case $m = 2$, can be viewed as representations of complex numbers using a complex number base with digits in $\mathbb{Z}^2$, with little redundancy. Among such expansions, we found a lot of systems whose associated symbolic dynamics is sofic in [1], which immediately give rises to construction of self-similar tilings using a finite number of polygons and their translations. Note that the construction of self-similar tilings is an interesting difficult problem on its own ([18, 35, 21, 19]), which gives us a motivation of the study of rotational beta expansion.

In the study of the ergodic properties of these number theoretic expansions, the most prior subject is the existence and the uniqueness of the absolutely continuous invariant probability measure (henceforth, referred as ACIM) of the underlying dynamical system. Renyi [27] proved that the beta transformation $T(x) = \beta x \bmod 1$ admits a unique ACIM, and it is equivalent to the Lebesgue measure. Later, Parry [24] gave the explicit form of this invariant density. His idea is to find an explicit fixed point of the associated Perron-Frobenius operator. In the same line [26, 25, 9, 11] gave the explicit forms of the ACIM of similar piecewise expanding maps. By the simple feature of these maps that the forward orbits of the discontinuities fall into a single point, it follows that the ACIM is unique and therefore the system becomes ergodic (c.f. [22]). For negative beta expansion, the ACIM is not always equivalent to the Lebesgue measure. Liao-Steiner [23] studied the gaps between the supports (intervals) of the ACIM. Considering an appropriate skew product of beta expansions, we can study randomized system and their invariant measures (see [7, 17]).

Summing up, we know a lot on one dimensional beta expansions. Ergodic study becomes drastically involved if we move to higher dimensions, by the effect of higher dimensional discontinuities. By this difficulty, there are not so many results on the basic properties of higher dimensional 'handy' expansion, although there are many number theoretical trials mentioned above. This gives another motivation to study rotational beta expansions. Since T is a piecewise expanding map, a general theory in [15, 16, 10, 29, 33, 6, 34] tells us that there exists at least one and at most a finite number of ergodic ACIM's, whose supports have disjoint interiors (c.f. [29]). On the other hand, uniqueness of ACIM fails to hold in general rotational beta expansions. In [1] we studied the case $m = 2$ and $M \in SO(2)$ and showed among others that T has an ACIM equivalent to 2-dimensional Lebesgue measure when β is larger than a certain bound depending only on $\mathcal{X}$.

A *strip* is the closed region sandwiched by two parallel hyperplanes of co-dimension one. Its *width* is the distance between the two hyperplanes. Define the *width* of a non empty set $A \subset \mathbb{R}^m$ by the minimum width of strips which contain A , and denote it by $w(A)$. Let $r(P)$ be the *covering radius* of a point set $P \subseteq \mathbb{R}^m$, i.e., $r(P) = \sup_{x \in \mathbb{R}^m} \inf_{y \in P} \|x - y\|$. The values $w(A)$ or $r(P)$ can be ∞ if no such value exists in $\mathbb{R}$. Define a property

(S) For any $z \in \mathcal{X}$ there exists $n \in \mathbb{N}$ that $2r(T^{-n}(z) + \mathcal{L}) \leq \beta w(\mathcal{X})$.

This property is confirmed in many cases in a stronger form that there exists $n \in \mathbb{N}$ that for any $z \in \mathcal{X}$ we have $2r(T^{-n}(z) + \mathcal{L}) \leq \beta w(\mathcal{X})$. For instance, if $2r(\mathcal{L}) \leq \beta w(\mathcal{X})$, then the last condition is valid with $n = 0$, because $r(z + \mathcal{L}) = r(\mathcal{L})$. In this paper we shall prove

Theorem 1.1. *Assume that the property (S) holds. If $\beta \geq m + 1$, then $(\mathcal{X}, T)$ has a unique ACIM. This ACIM is equivalent to the m -dimensional Lebesgue measure.*

The proof of Theorem 1.1 depends on a beautiful result of Bang [5], which gave an affirmative answer to the conjecture of Tarski on the covering of a convex body by strips.

Remark 1.2. The property (S) guarantees that for any $z \in \mathcal{X}$, $\mathcal{X} \setminus T^{-n-1}(z)$ can not contain an open ball of radius $w(\mathcal{X})/2$. In fact, from $\beta M(T^{-n-1}(z)) = \beta M(\mathcal{X}) \cap V$ for $V := \{y + d \mid y \in T^{-n}(z), d \in \mathcal{L}\}$, if there is a ball of radius $\beta w(\mathcal{X})/2$ in $\beta M(\mathcal{X}) \setminus V$ then its center is at least $\beta w(\mathcal{X})/2$ away from any point of V , giving a contradiction. The property (S) is easy to show in many cases. However (S) is not always true, since it is easy to give a counter example when T is not surjective for $m > 1$.

Remark 1.3. For $m = 1$ we have $r(\mathcal{L}) = w(\mathcal{X})/2$ and the assumptions are reduced to $2 \leq \beta$. On the other hand [3] showed that the symmetric beta expansion

$$U : x \mapsto \beta x - \left\lfloor \beta x + \frac{1}{2} \right\rfloor$$

in $[-1/2, 1/2)$ does not have an ACIM equivalent to 1-dimensional Lebesgue measure if $\beta < 2$. This shows that the bound $m + 1$ in Theorem 1.1 is best possible for $m = 1$.

To prove Theorem 1.1, we introduce an idea to look at the *hole* in $\mathcal{X}$ in dealing with ACIM, whose definition is found in §3. By the same idea, one can improve the lower bound when an additional condition is satisfied.

Theorem 1.4. *Assume that the property (S) holds and there is an $\eta \in \mathcal{L}$ such that*

$$\beta M\mathcal{X} \subset \bigcup_{j \in \mathbb{Z}} (\mathcal{X} + j\eta).$$

If $\beta > 2$, then $(\mathcal{X}, T)$ has a unique ACIM. This ACIM is equivalent to the m -dimensional Lebesgue measure.

As a corollary to this result, we discuss a family of rotational beta transformations defined in the complex plane, which was introduced by Klaus Scheicher and Paul Surer [30]. Let $\beta > 1$. Let $\zeta \in \mathbb{C} \setminus \mathbb{R}$ where $|\zeta| = \beta$. Consider $\mathcal{X} = \{x + (-\bar{\zeta})y \mid x, y \in [0, 1)\}$. Let T_ζ be the rotational beta transformation on $\mathcal{X}$ given by $z \mapsto \zeta z - d$ where $d = d(z) \in \mathcal{L} = \mathbb{Z} + (-\bar{\zeta})\mathbb{Z}$. For $\theta \in (0, \pi)$, define

$$C(\theta) := \sqrt{\frac{1 + \sqrt{1 + 4 \sin^4(\theta)}}{2 \sin^2(\theta)}}.$$

Corollary 1.5. *If $\beta > \max\{2, C(\theta)\}$, then $(\mathcal{X}, T_\zeta)$ has a unique ACIM. This ACIM is equivalent to the 2-dimensional Lebesgue measure.*

One can check that, in particular, if $\theta \in [\sin^{-1}(2/\sqrt{15}), \pi - \sin^{-1}(2/\sqrt{15})]$ then the corollary holds for all $\beta > 2$.

Specializing our technique to $m = 2$, we obtain an alternative proof of Theorem 1 in [1]. Let $\eta_1, \eta_2, \xi \in \mathbb{R}^2$ and

$$\mathcal{X} = \{\xi + x_1\eta_1 + x_2\eta_2 \mid x_i, x_2 \in [0, 1)\}$$

be a fundamental domain of the lattice $\mathcal{L} = \mathbb{Z}\eta_1 + \mathbb{Z}\eta_2$ in $\mathbb{R}^2$. We fix an isometry $M \in O(2)$ to define the map T . Denote by $\theta(\mathcal{X}) \in (0, \pi)$

the angle between η_1 and η_2 . Define for $\theta = \theta(\mathcal{X}) \in (0, \pi/2]$,

$$B_1 = B_1(\theta) := \begin{cases} 2 & \text{if } \frac{1}{2} < \tan(\theta/2) \\ 1 + \frac{2}{1+\sin(\theta/2)} & \text{if } \sin(\theta) < \sqrt{5} - 2 \\ \frac{3}{2} + \frac{\cot^2(\theta/2)}{16} + \tan^2(\theta/2) & \text{otherwise} \end{cases}$$

and

$$B_2 = B_2(\theta) := \begin{cases} 1 + \frac{1}{\sin(\theta(\mathcal{X})) \cos(\theta/2)} & \text{if } \frac{\pi}{3} < \theta \\ 1 + \frac{2}{1+\sin(\theta/2)} & \text{otherwise.} \end{cases}$$

For $\theta(\mathcal{X}) \in [\pi/2, \pi)$, define $B_i(\theta) := B_i(\pi - \theta)$, ($i = 1, 2$).

Theorem 1.6. *Assume that $m = 2$ and (S) is valid. If $\beta > B_1$ then $(\mathcal{X}, T)$ has a unique ACIM μ . Moreover, if $\beta > B_2$ then μ is equivalent to the 2-dimensional Lebesgue measure.*

One can confirm the inequality $B_1 \leq B_2 < 3$ in Figure 1.

FIGURE 1. Comparison of B_1 and B_2

In fact, Theorem 1.6 is an improvement of Theorem 1 in [1]. First, it works not only for rotations but also for reflections. Second the value of B_1 and B_2 are improved when $\min\{\theta(\mathcal{X}), \pi - \theta(\mathcal{X})\}$ is small, and became uniformly bounded by 3, the bound given by Theorem 1.1. It is interesting that we retrieve the bound in [1] when $\theta(\mathcal{X})$ is close to $\pi/2$, though the methods are pretty different.

Remark 1.7. To illustrate Theorem 1.6, we discuss a simple family of rotational beta expansions. Let $\mathcal{X} = [-1/2, 1/2) \times [-1/2, 1/2)$. Define T to be the rotational beta expansion on $\mathcal{X}$ where the isometry M is the identity. The map T is a Cartesian product of two identical maps U :

$[-1/2, 1/2) \rightarrow [-1/2, 1/2)$ in Remark 1.3. If $\beta < 2$, then the support of the ACIM of U is contained in $Z = [-1/2, \beta/2 - 1] \cup [1 - \beta/2, 1/2]$. Clearly the support of the ACIM of T is contained in $Z \times Z$ and the ACIM is not equivalent to the 2-dimensional Lebesgue measure. Let $\beta \leq \sqrt{2}$ and consider the restrictions of T in Y_1 and Y_2 , where Y_1 is composed of eight squares of size $(\beta - 1)/(\beta(\beta + 1))$ and $(\beta - 1)/2(\beta + 1)$ and Y_2 is composed of eight $(\beta - 1)/(\beta(\beta + 1)) \times (\beta - 1)/2(\beta + 1)$ rectangles as in Figure 2. We easily confirm that in Y_1 , a small square is mapped by T into the diagonally opposite big square while a big square is mapped to the four corner squares. Hence, T has an ACIM whose support is in Y_1 . Likewise, the restriction of T on Y_2 is well-defined and T has at least two ergodic components. This is an interesting example that 1-dimensional map U has a unique ACIM for every $\beta > 1$ by the discussion of [22], but its Cartesian product T has at least two ACIM's when $\beta \leq \sqrt{2}$. Consequently the projections of different 2-dimensional ACIM's of T to the first coordinate are identical. This phenomenon is explained by the fact that U is not totally ergodic; by the ACIM of U , U is ergodic but U^2 is not. We can also construct isomorphic transformations where the fundamental domain is a rhombus of side length 1, $\theta(\mathcal{X}) \in (0, \pi)$ and whose diagonals meet at the origin. Meanwhile, we know that the unique ACIM preserved by U is equivalent to the Lebesgue measure when $\beta \geq 2$ as mentioned in Remark 1.3. Thus, when $\beta \geq 2$, T admits a unique ACIM and this measure is equivalent to the 2-dimensional Lebesgue measure. Having these examples, we know $B_2 \geq 2$ and $B_1 > \sqrt{2}$ are necessary in Theorem 1.6.

FIGURE 2. Y_1 (Left) and Y_2 (Right)

2. PROOF OF THEOREM 1.4

It is helpful for readers to start from the proof of Theorem 1.4. In order to show that there exists an ACIM equivalent to Lebesgue measure, as in [1], it is enough to prove that $\bigcup_{i=1}^{\infty} T^{-i}(z)$ is dense in $\mathcal{X}$ for any $z \in \mathcal{X}$. Since $\mathcal{X}$ is bounded, the set of pairs $(x, r) \in \mathcal{X} \times \mathbb{R}_{\geq 0}$ such that an open ball $B(x, r)$ is entirely contained in $\mathcal{X} \setminus \bigcup_{i=1}^n T^{-i}(z)$ forms a compact set. Hereafter such a ball is called a *hole of n -th level*. Let r_n be the maximum radius of the holes of n -th level. Fix $z \in \mathcal{X}$. Suppose that $\mathcal{X} \setminus T^{-n}(z)$ does not contain a ball of radius $w(\mathcal{X})/2$ for some $n \in \mathbb{N}$.

Since

$$(2.1) \quad \beta M(T^{-n-1}(z)) = \beta M(\mathcal{X}) \cap \bigcup_{d \in \mathcal{L}} (T^{-n}(z) + d)$$

and

$$\beta M(\mathcal{X}) \subset \bigcup_{i \in \mathbb{Z}} (\mathcal{X} + i\eta),$$

we consider the maximum open ball $B(x, r)$ contained in

$$\bigcup_{i \in \mathbb{Z}} i\eta + (\mathcal{X} \setminus T^{-n}(z)).$$

By (2.1), we have $r_{n+1} = r/\beta$. Note that the largest hole $B(x, r)$ intersects $\bigcup_{i \in \mathbb{Z}} \partial(\mathcal{X}) + i\eta$ at most once with a hyperplane $(\mathcal{X} + i\eta) \cap (\mathcal{X} + (i+1)\eta)$. In fact, if it intersects both $(\mathcal{X} + i\eta) \cap (\mathcal{X} + (i+1)\eta)$ and $(\mathcal{X} + (i+1)\eta) \cap (\mathcal{X} + (i+2)\eta)$, then $B(x, r)$ contains a segment of length greater than $w(\mathcal{X})$ and the radius of the ball should be greater than $w(\mathcal{X})/2$, which is not possible. We claim that if $r > 2r_n$, then $B(x, r) \subset \beta M(\mathcal{X})$ must contain an element $y \in \bigcup_{i \in \mathbb{Z}} (T^{-n}(z) + i\eta)$. If not, then since a hemisphere of $B(x, r)$ belongs to one side of the hyperplane, there is a ball of radius not less than $r/2$ in $\mathcal{X}$ which does not contain an element of $T^{-n}(z)$ (see Figure 3). However $r/2 > r_n$ gives a contradiction, showing the claim. Thus we have seen that $r \leq 2r_n$. From $r_{n+1} = r/\beta$, we get $r_{n+1} \leq 2r_n/\beta$. Iterating this procedure, we see that $\lim_{n \rightarrow \infty} r_n = 0$. This finishes the proof.

3. PROOF OF COROLLARY

Let $z \in \mathcal{X}$. Since $\beta^2 > 2$, the region $\zeta\mathcal{X}$ must contain at least two integer translates of z , aligned with distance 1. We find at least two points in $T^{-1}(z)$ aligned with distance $1/\beta$ in a line of slope being the argument of $-\bar{\zeta}$ of $\mathcal{X}$. Let L be the line segment connecting the midpoints of the longer sides of $\mathcal{X}$ and choose $x \in T^{-1}(z)$ closest to L .

FIGURE 3. The largest hole in $\beta M(\mathcal{X})$ can not be doubled.

Then, the segment of slope $-\bar{\zeta}$ starting from x and ending at a point in L is of length at most $1/(2\beta)$. Let us consider a circle of radius $\beta w(\mathcal{X})/2 = \beta \sin(\theta)/2$ inscribed in $\zeta\mathcal{X}$ as in Figure 4. We consider the diameter parallel to the longer side of $\zeta\mathcal{X}$. Parallel to this diameter, we look at the chord of the circle extending to x of length $2h$. Observing the right triangle of hypotenuse equal to the radius of the circle, a side of length h and the other is of length at most $\sin(\theta)/(2\beta)$, we see

$$h \geq \sqrt{(\beta \sin(\theta)/2)^2 - (\sin(\theta)/(2\beta))^2}.$$

Clearly, if $h > 1/2$, then the chord is of length greater than 1 and it contains a translate $x + d$ with $d \in \mathbb{Z}$. Hence, an open ball of radius $w(\mathcal{X})/2$ in $\mathcal{X}$ must contain a point of $T_\zeta^{-2}(z)$. Thus if $\beta > \max\{\sqrt{2}, C(\theta)\}$ then $\mathcal{X} \setminus T_\zeta^{-2}(z)$ can not contain an open ball of radius $w(\mathcal{X})/2$. Applying the proof of Theorem 1.4 we get the desired result.

FIGURE 4. T_ζ when $\zeta = \beta \exp(3\pi\sqrt{-1}/4)$

4. TARSKI'S PLANK PROBLEM AND DISSECTION OF A BALL

In this section we prepare a lemma to prove Theorem 1.1. Motivated by the minimum dissection of piecewise congruent polygons, A. Tarski [32] asked if a convex set X is entirely covered by a set of strips (planks) of width w_i ($i = 1, \dots, k$) whether $\sum_{i=1}^k w_i \geq w(X)$ must hold. This

problem is called Tarski's plank problem. T. Bang [5] gave an affirmative answer to this question with an ingenious proof. Our lemma is closely related to this result. Consider a unit ball B in $\mathbb{R}^m$ and k hyperplanes of co-dimension one which cut the ball B into convex cells. We are interested in the maximum of the radius of open balls which can be inscribed in such cells.

Lemma 4.1. *For arbitrary configurations of k hyperplanes, there exists an open ball of radius $1/(k+1)$ inscribed in a cell generated by the k hyperplanes and a m -dimensional unit ball. The maximum radius of the balls in the cells attains its minimum $1/(k+1)$ only when the k hyperplanes are parallel and totally aligned by distance $2/(k+1)$.*

The first statement is found in Ball [4] as well.

Proof. Consider a ball W of radius $1 - 1/(k+1) = k/(k+1)$ and a unit ball B , both centered at the origin. For a hyperplane H_i ($i = 1, 2, \dots, k$), we associate a strip $P_i(\varepsilon)$ whose points are of distance not greater than $1/(k+1) - \varepsilon$ from H_i with a small positive constant ε . Since

$$k(2/(k+1) - 2\varepsilon) < 2k/(k+1)$$

by Bang's result, we have $W \setminus \bigcup_{i=1}^k P_i(\varepsilon) \neq \emptyset$. Choosing a center from this non-empty set, we find an open ball of radius $1/(k+1) - \varepsilon$ entirely contained in a cell generated by B and H_i ($i = 1, \dots, k$). Taking ε smaller, we obtain a decreasing sequence of non empty compact sets $W \setminus \bigcup_{i=1}^k \text{Int}(P_i(\varepsilon))$. Thus the set $\bigcap_{\varepsilon>0} W \setminus \bigcup_{i=1}^k \text{Int}(P_i(\varepsilon))$ is non empty and we obtain an open ball of radius $1/(k+1)$ entirely contained in a cell generated by B and H_i ($i = 1, \dots, k$).

The remaining part of the proof depends more on the method by Bang. A key of the proof of [5] is that $\bigcap (W \pm u_1 \pm u_2 \cdots \pm u_k) \neq \emptyset$, where u_i is a vector of length $1/(k+1) - \varepsilon$ perpendicular to the hyperplanes of the strip $P_i(\varepsilon)$. The intersection is taken over all possible choices of signs. This fact is valid even when $\varepsilon = 0$, if not every H_i are parallel. In fact, without loss of generality, we may assume that H_i are parallel for $1 \leq i \leq t < k$ and H_j ($j > t$) are not parallel to H_1 . Then $\bigcap (W \pm u_1 \pm u_2 \cdots \pm u_t)$ is simply a lens shape $L := (W - tu_1) \cap (W + tu_1)$ whose width $2(k-t)/(k+1)$ is attained only by the hyperplanes tangent to the two tops of the lens L (see Figure 5). From the proof of [5], we see that $\bigcap (L \pm u_{t+1} \cdots \pm u_k) \neq \emptyset$ contains a translation of κL with $\kappa > 0$, because and the minimal strip perpendicular to u_j which contain L has width greater than $w(L)$ for $j > t$. Following the proof of Bang, we know that $P_i(0)$ ($i = 1, \dots, k$) do not entirely cover W . Therefore if

FIGURE 5. Lens shape and its minimum strip

not all H_i 's are parallel, we can find a ball of radius strictly larger than $1/(k+1)$ entirely contained in a cell. $\square$

5. PROOF OF THEOREM 1.1

We proceed in the same manner as Theorem 1.4. We will prove that $\bigcup_{i=1}^{\infty} T^{-n}(z)$ is dense in $\mathcal{X}$ for any $z \in \mathcal{X}$ by showing that the maximum radius r_n of the holes of n -th level converges to 0. From (2.1), we wish to get the maximum of the radius r of the ball $B(x, r) \subset \beta M(\mathcal{X})$ which does not contain any element of $\bigcup_{d \in \mathcal{L}} (T^{-n}(z) + d)$. By Remark 1.2, such a ball can not intersect two parallel hyperplanes which contain $m-1$ dimensional faces of $\partial(\mathcal{X}) + d$ for $d \in \mathcal{L}$. Therefore $B(x, r)$ is cut by at most m hyperplanes H_i ($i = 1, \dots, m$), each of which contain a face of some translation $\partial(\mathcal{X}) + d$ with $d \in \mathcal{L}$. Lemma 4.1 shows there is an inscribed ball of radius $r/(m+1)$ in some cell. Thus we see within $B(x, r)$, there is a ball of radius $r/(m+1)$ inscribed in $\mathcal{X} + d$ with $d \in \mathcal{L}$ having no point of $T^{-n}(z) + d$, which implies $r/(m+1) \leq r_n$. As $r_{n+1} = r/\beta$, we have $r_{n+1} \leq (m+1)r_n/\beta$, which gives the conclusion for $\beta > m+1$.

Finally we discuss the case $\beta = m+1$. If $m \geq 2$, any pair of the m hyperplanes are not parallel and Lemma 4.1 shows for any ball $B(x, r) \subset \beta M(\mathcal{X})$ there is the largest hole of radius strictly greater than $r/(m+1)$, which shows that the assertion is still valid for $\beta = m+1$. For $m = 1$, the problem is reduced to the study of the map

$$T(x) = 2x + a - \lfloor 2x + a \rfloor \text{ or } T(x) = -2x + a - \lfloor -2x + a \rfloor$$

defined in $[0, 1)$ where 1-dimensional Lebesgue measure is clearly the ACIM.

6. PROOF OF THEOREM 1.6

Throughout this section, we assume $\xi = 0$ because the proof is identical for all ξ . As in [1], B_i ($i = 1, 2$) are symmetric with respect to $\theta(\mathcal{X}) \leftrightarrow \pi - \theta(\mathcal{X})$, we prove the case $0 < \theta(\mathcal{X}) \leq \pi/2$. Let us show the bound B_2 . Similar to the proofs of Theorem 1.4 and 1.1, in view of (2.1) we wish to find the infimum radius r that for every ball

$B(x, r) \subset \beta M(\mathcal{X})$, there exists a $d \in \mathcal{L}$ such that $B(x, r) \cap (\mathcal{X} + d)$ contains a ball of radius r_n under the knowledge of $\theta(\mathcal{X})$. Then r_{n+1} can be chosen to be r/β . An equivalent dual problem is to find the supremum of r that one can find a ball $B(x, r) \subset \beta M(\mathcal{X})$ that for all $d \in \mathcal{L}$, $B(x, r) \cap (\mathcal{X} + d)$ does not contain a ball of radius r_n . Clearly the supremum is attained by the configuration that for at least one $d \in \mathcal{L}$ the boundary of $B(x, r) \cap (\mathcal{X} + d)$ is circumscribed about a ball of radius r_n . If there is only one line passing through $B(x, r)$, then the supremum would be $2r_n$ as Theorem 1.4, or in Figure 3. Since $B_2 > 2$ for any $\theta(\mathcal{X})$, we will see that this case does not give the supremum. By Remark 1.2, the ball $B(x, r)$ intersects at most two non parallel hyperplanes (lines).

Let us consider the case that $B(x, r)$ intersects the two lines. For example, in Figure 6, the ball $B(0, r)$ is touching two maximal balls of radius r_n in the cells. However, this configuration does not give the supremum, because shifting a little the ball $B(0, r)$ along the bisector of the acute angle, we easily see that every cell no longer contains a ball of radius r_n . Since a planar circle is determined by three intersections, by

FIGURE 6. Non supremum configuration

similar small perturbation argument, in the supremum configuration $\partial(B(x, r))$ must touch $B(y_i, r_n)$ ($i = 1, 2, 3$) where $B(y_i, r_n)$ are the balls inscribed in three distinct $\mathcal{X} + d_i$ with $d_i \in \mathcal{L}$. Each $B(y_i, r_n)$ is a maximal ball within a cell in $\partial(\mathcal{X}) + d_i$. There are exactly two possible supremum configurations as depicted in Figure 7(a) and 7(b).

Figure 7(a) is for $\theta(\mathcal{X}) < \pi/3$. Points A, B are the centers of the corresponding balls, BH is the perpendicular from B to x -axis and AD is parallel to x -axis which intersects BH . Since $AC = r$, $BC = BH = r_n$, putting $\ell = DH$, we have

$$r = \ell + 2r_n, \quad \frac{r_n - \ell}{r_n + \ell} = \sin \left(\frac{\theta(\mathcal{X})}{2} \right)$$

FIGURE 7. Two possible supremum cases

and we obtain

$$\frac{r}{r_n} = 1 + \frac{2}{1 + \sin(\theta(\mathcal{X})/2)}.$$

For $\theta(\mathcal{X}) \geq \pi/3$ by the configuration of Figure 7(a), the above circle intersects x -axis and the circle below intersects the line of slope $\theta(\mathcal{X})$. Therefore we have to switch to Figure 7(b). The point A is the center of the ball of radius r , whose radius is given by $AC = r$, and the points B, D are the ones of radius r_n and O is the origin. The segments BH, DK are the perpendiculars from B, D to x -axis. JI is a segment passing through A and parallel to x -axis connecting the two perpendiculars. Then we have

$$KH = KO + OH = \frac{r_n}{\cot(\theta(\mathcal{X})/2)} + \frac{r_n}{\tan(\theta(\mathcal{X})/2)}$$

$$r = AB + r_n$$

$$AB \cos(\theta(\mathcal{X})/2) = AI = AD \cos(\theta(\mathcal{X})/2) = AJ = KH/2.$$

Solving these equations we get

$$\frac{r}{r_n} = 1 + \frac{\cot(\theta(\mathcal{X})/2) + \tan(\theta(\mathcal{X})/2)}{2 \cos(\theta(\mathcal{X})/2)}$$

which turned out to be equal to

$$1 + \frac{1}{\sin(\theta(\mathcal{X})) \cos(\theta(\mathcal{X})/2)}$$

appeared in Theorem 1.1 of [1]. Next we prove the bound B_1 . Our target is to show the same statement in the proof of Theorem 1.1 in [1]:

If $\beta > B_1$, then for any $\varepsilon > 0$ there exists $z \in \mathcal{X} \setminus \bigcup_{i=-\infty}^{\infty} T^i(\partial(\mathcal{X}))$ and a positive integer n that $\bigcup_{i=0}^n T^{-i}(z)$ is an ε -covering of $\mathcal{X}$

by choosing a point z very close to the origin. In showing the bound B_1 , it is practically the same as assuming $z = 0$ and the points of $\mathcal{L}$ can not be an inner point of $B(x, r)$. Thus our geometry problem has an additional restriction that the ball $B(x, r)$ can not contain the origin as an inner point. Let us start with Figure 7(a). In this figure, the origin is outside of $B(x, r)$ and there is no change. However, when we make $\theta(\mathcal{X})$ gradually large, we find at some angle the large circle passes through the origin as in Figure 8(a). This happens when additionally

$$\frac{r_n}{\sin(\theta(\mathcal{X})/2)} = r + \ell + r_n$$

holds, i.e., when $\sin(\theta(\mathcal{X})/2) = \sqrt{5} - 2$. If $\sin(\theta(\mathcal{X})/2) > \sqrt{5} - 2$, the supremum configuration is switched to Figure 8(b).

FIGURE 8. Change of supremum configurations

This is the configuration that $\partial(B(x, r))$ passes through the origin and touches $B(y_i, r_n)$ ($i = 1, 2$) where $B(y_i, r_n)$ are the balls inscribed in two distinct $\mathcal{X} + d_i$ with $d_i \in \mathcal{L}$. Each $B(y_i, r_n)$ is a maximal ball in a cell in $\partial(\mathcal{X}) + d_i$. The point A is the center of the ball of radius r whose radius is given by $AO = r$, B is the center of the ball of radius r_n and O is the origin. The segments AK and BH are perpendiculars from A and B , respectively, to the line of slope $\tan(\theta(\mathcal{X}))$. The segment AC is parallel to the line and intersects BH . Putting $AK = CH = \ell$, we

have

$$\begin{aligned}
r &= \ell + 2r_n \\
OK^2 &= r^2 - \ell^2 \\
AB &= r_n + \ell \\
BC &= r_n - \ell \\
AC &= KH = \sqrt{4r_n\ell} \\
OH &= OK + KH = \frac{r_n}{\tan(\theta(\mathcal{X})/2)}.
\end{aligned}$$

Summing up, we obtain

$$\frac{r}{r_n} = \frac{3}{2} + \frac{1}{16} \cot^2\left(\frac{\theta(\mathcal{X})}{2}\right) + \tan^2\left(\frac{\theta(\mathcal{X})}{2}\right).$$

This configuration works provided $OK \leq OH$. The next critical configuration is depicted in Figure 9(a).

FIGURE 9. Critical configuration and beyond

It is plain to confirm from Figure 9(a) that the case of Figure 8(b) appears only when $\tan(\theta(\mathcal{X})/2) \leq 1/2$. For the case $1/2 < \tan(\theta(\mathcal{X})/2)$, the maximal ball inscribed in the cell bounded by x -axis and the line of slope $\tan(\theta(\mathcal{X}))$ does not touch the x -axis as in Figure 9(b). Therefore the configuration is reduced to the case of Theorem 1.4, i.e., $B(x, r)$ is cut essentially by a single line, and we get $r/r_n = 2$. All the statements of Theorem 1.6 are proved.

Acknowledgments.

We would like to express our gratitude to Peter Grabner and Wöden Kusner who informed us of the result of Bang, which made Theorem

1.1 in the present form. The first author is indebted to Hiroyuki Tasaki for stimulating discussion. The authors are supported by the Japanese Society for the Promotion of Science (JSPS), Grant in aid 21540012. The second author expresses his deepest gratitude to the Hitachi Scholarship Foundation.
